Abstract

Background: The meticulous identification of the hepatobiliary tree system normal anatomy during surgical operations is crucial in iatrogenic injury prevention. Equally important, an understanding of the congenital variations of biliary and vascular anatomy, as the literature abounds with reports of specific anatomical variations, and their surgical implications.

Aim: This study aimed to study the presence of anatomical variations within the hepatobiliary system in Sudanese population undergoing endoscopic retrograde cholangiopancreatography (ERCP).

Patients and methods: The records of patients undergoing ERCP in Soba University Hospital during 2004 to 2008 were analyzed. There were 277 Sudanese patients who had complained of right hypochondrial abdominal pain & history of jaundice (obstructive jaundice) that underwent ERCP were included in this study. The exclusion criteria included the following: Sudanese patients in whom ERCP failed or patients who had advanced hepatobiliary disease like cancers, strictures either cancerous or iatrogenic, fistula and iatrogenic biliary leak.

Results: The analysis of 277 Sudanese patients undergoing ERCP of the hepatobiliary system showed the following results regarding the variations: The choledochal cyst type I ( fusiform type ) was present in 3 (1.08%) patients; very low cystic duct insertion (parallel) was present in 1 ( 0.36%) patient and long cystic duct was present in 3 (1.08%) patients. The ampulla of Vater size variations occurred as A) Normal in 158 (57%) patient, B) Small in 56 (20.2%) patients, C) Large in 29 (10.5%) patients, D) Periampullary diverticula in 4 (1.4%) patients and E) unclassified in 30 (10.8%) patients. Other forms of congenital anomalies were not found.

Conclusion: The using of endoscopic retrograde cholangiopancreatography (ERCP) is a reliable radiological method for detecting congenital anomalies of the hepatobiliary system, but it is an invasive procedure.

1. Introduction

The meticulous identification of the hepatobiliary tree system normal anatomy during surgical operations is crucial in iatrogenic injury prevention. Equally important, an understanding of the congenital variations of biliary and vascular anatomy, as the literature abounds with reports of specific anatomical variations, and their surgical implications (Williams 1980). In recent years the technology had developed and the using of imaging modalities gave the possibility to study the hepatopancreatic-biliary system includes computed tomography (CT) scans, magnetic resonance cholangiopancreatography (MRCP), percutaneous transhepatic cholangiography (PTC), contrast-enhanced (MRCP) and intraoperative cholangiography (Nayman and Özbek 2016). Endoscopic cannulation of the ampulla of Vater was first reported in 1968. Since that time, the endoscopic retrograde cholangiopancreatography (ERCP) was established worldwide rapidly and became a very useful tool for diagnosis and therapy in biliary and pancreatic diseases. In clinical practice, sphincterotomy was beginning to use in the mid-1970s and biliary stenting five years after that (Leung 2005).

This study reviews the congenital variations of extrahepatic biliary anatomy in Sudanese patients undergoing endoscopic retrograde cholangiopancreatography (ERCP). Further studies on image techniques and hepatobiliary scintigraphy for diagnosis of biliary diseases may details of the whole biliary ductal system and show some kinds of biliary malformation, which are clinically important such as an abnormal arrangement of the pancreatico-biliary ductal system, congenital biliary strictures and congenital dilatation of the intrahepatic bile duct associated with choledochal cyst.

2. Patients and methods

This is a descriptive – retrospective hospital-based study carried at the Soba University Hospital; Sudan for four years. The author collected data from records of patients undergoing (ERCP) at Soba University Hospital during 2004 to 2008. There were 277 Sudanese patients who had complained of right hypochondrial abdominal pain & history of jaundice (obstructive jaundice) that underwent ERCP were included within this study. The exclusion criteria included the following: Sudanese patients in whom ERCP failed or patients who had advanced...
hepatobiliary disease like cancers, strictures either cancerous or iatrogenic, fistula and iatrogenic biliary leak. Patients were referred by consultants got an appointment, and the procedure was explained and consent was taken for the hospital administration to collect data from these patients and given an explanation for preparation include fasting 6 hours at least. Investigations are ready, which are bleeding time, hemoglobin (Hb%), blood grouping, platelets count and ultrasound images. Then patients go to the comfortable X-ray room containing side view duodenoscope Olympus CLV –U 40 and appropriate ERCP accessories as catheters, contrast and emergency drugs. Before the procedure, the patients were asked to remove dentures, eye glasses and contact lenses. Then they were asked about the history of any allergic reactions to any medications or contrast dye. Diathermy cuff was put under the upper-right leg. After wearing a hospital gown, the patient was asked to lie on x-ray table, the left arm behind his back to facilitate rotating into the prone position (Oblique prone position). Endoscopist & their assistants wear a protective lead apron, and then started the procedure after sedating patient intravenously with pethedin 25mg and diazepam 5mg. Endoscopic tube was introduced through mouth/esophagus/stomach until it reaches second part of duodenum, then the ampulla was identified. Cholangiographic catheter was introduced & radiocontrast dye injected to common bile duct & extrahepatic ducts until reach intrahepatic ducts. Selected still images obtained on X-ray film and the film preparation was done by radiology technicians using X-ray machine KXO – ISE model and X-Omat film processor. The interpretation of radiological film was carried out by senior endoscopist.

Then the data were arranged on a master sheet. The author analyzed data using the computer program (SPSS) version 15.1 for evaluation of the results.

3. Results

In this study of 277 cases, 156 (56.3%) were females and the remaining 121 (43.7%) were males, and the majority of anatomical variations present in our study seen in females, (Table 1). The peak incidence of patient's age for the hepatobiliary system variations discovery was ranged between 46 - 60yrs (middle age), which represent 30.68%, (Figure 2).

The analysis of 277 Sudanese patients undergoing ERCP of the hepatobiliary system showed the following results regarding the variations: The choledocal cyst type 1 (fusiform type) was present in 3 (1.08%) patients; very low cystic duct insertion (parallel) was present in 1 (0.36%) patient and the long cystic duct was present in 3 (1.08%) patients, (Table 2).

The ampulla of Vater size variations occurred as A) Normal in 158 (57%) patient, B) Small in 56 (20.2%) patients, C) Large in 29 (10.5%) patients, D) Periampullary diverticula in 4 (1.4%) patients and E) unclassified in 30 (10.8%) patients, (Table 3). Other forms of congenital anomalies were not found in this study.

4. Discussion

When performing any hepatobiliary procedure, the frequent congenital variations full knowledge is required for iatrogenic injury prevention. In Sudan, no postmortem study, the high cost of magnetic resonance image (MRI) and intraoperative cholangiography not done as routine investigation just in a few centers. The endoscopic retrograde cholangiopancreatography (ERCP) is a direct contrast study of the pancreatic and hepatobiliary tree system. It is beneficial in the diagnosis and treatment of diseases such as developmental anomalies, strictures, and stones. Accordingly, the present study focuses on the presence of anatomical variations of the hepatobiliary system by analyzing ERCP cases from (2004-2008). The total cases are 277 presented as 2004 (8 cases), 2005 (10 cases), 2006 (58 cases), 2007 (65 cases) and 2008 (136 cases), (Figure 1). Out of the 277 cases, 121(43.7%) were males and 156 (56.3%) were females, (Table 1). The majority of variations present in our study seen in females, and this result goes with the literature. Furthermore, another study revealed cystic duct variations appeared higher with female gender 66.67% than the males 33.34% (Ahmad et al. 2016). Also, the choledochal cyst is more prevalent in females than males by a ratio over the range of 3:1 to 4:1 (Sarin et al. 1994).

The peak incidence of patient's age for the hepatobiliary system variations discovery was ranged between 46-60yrs (middle age), which represent 30.68%. Previous studies reviewed did not mention the age, (Figure 2). The anatomical variations of the cystic duct are usually of no clinical significance. We found one case (0.36 %) had a very low cystic duct insertion in common hepatic duct, (Table 2). This less than figures found in international data. This variation incidence varied from 8.3% to 14% in an autopsy series (Lamah 2001). In Korea, 10,243 ERCP cases were studied in a prospective way showed the cystic duct variations in 16.9% of the patients. Low union with the common hepatic duct (CHD) found in 9% of cases and a spiral passing to the common hepatic duct either anteriorly or posteriorly in 7.9 % of patients (Kim et al. 2002). Also, we found long cystic duct in 3 (1.08 %) of cases, (Table 2). The cystic duct length measured from common bile duct up to gallbladder was 13.4-39 mm (27.4 mm on the average) (Myles 1937).

We reported in this study, gross dilatation (fusiform shape) in the middle of the common bile duct (CBD) in 3 (1.08 %) of cases diagnosed as choledochal cyst type one, (Table 2). The majority of cases were diagnosed in adult females complaining of right hypochondrial pain and jaundice. This result is very low when compared to the literature and the Todani classification, in which 80-90% of cases represent this type (Lipsett et al. 1997). In fact, 60-80% of adults with choledochal cysts had complications like stone formation and cystic wall carcinoma, especially type one choledochal cyst showed a higher cancer incidence (Ishibashi et al. 1997). In the clinical practice, wide (ERCP) utilization recognized increasingly the anatomical abnormalities of biliary system entry into the upper gastrointestinal tract. Our study revealed that common bile duct distal end terminated in the descending duodenum in all Sudanese patients included in this study. The anomalous opening of the common bile duct termination into the second part of the duodenal bulb was defined as the failure to demonstrate a papilla on its original site. Keddie et al. Investigated 120 patients and reported that common bile duct termination anomalies in 23% of cases. Another intraoperative cholangiograms study of biliary tract surgery for 1000 unselected patients showed that the common bile duct entered the descending duodenum in 86.9% of patients. It entered the junction between the descending and transverse duodenum,
and the transverse duodenum in 13.1% of cases (Keddie et al. 1974). There were studies of 100 dissections found no termination distal to the junction of the second and third parts of the duodenum. Furthermore, the termination of the common bile duct in the proximal portion of the third part of the duodenum in 16 of 196 cadavers represents about 8%. Through a standard duodenotomy, the authors found the common bile duct terminations at the junction of the second and third part of duodenum 11% and terminations in the proximal 2cm of the third part 11%. Hence, these studies showed that the anomalies of common bile duct terminations distal to descending duodenum is not rare (Davenport et al. 1991).

The position of the ampulla of Vater located at mid-point of the second part of the duodenal concave surface. Its size and shape are variable, and in different subjects, it may be round or oval, and either sessile or pedunculated. This study investigated the ampulla of Vater size variables in 277 patients, and revealed normal size in 158 (57%) patient, small size in 56 (20.2%) patients, large size in 29 (10.5%) patients, periampullary diverticula in 4 (1.4%) patients and unclassified in 30 (10.8%) patients, (Table 3). We reviewed the literature and there was no data found regarding the ampulla of Vater size variations. In 1930, there was an autopsies study conducted at the Mayo clinic showed that 58% of duodenal diverticula found near the ampulla (Myles 1937).

The using of ERCP in a study of 694 cases revealed periampullary diverticula in 162 (27.3%) of cases. Furthermore, 90.1% of cases increased seen after 50 years old and choledocholithiasis frequently saw in 58.5% (Chun 1997).

5. Conclusions

The using of endoscopic retrograde cholangiopancreatography (ERCP) is a reliable radiological method for depicting congenital anomalies of hepatobiliary system, but it is an invasive procedure.
