## Abstract

A patent-pending StormPav green pavement is introduced here as a form of permeable road, in which the system employed precast concrete pieces as modular units. The pavement layer consists of hexagonal plates with each a service inlet to drain water. This study is exploring the water draining capability or technically surface permeation of these service inlets. Virtual and physical modelling are performed to investigate the service inlets as multiple orifices to permeate surface water of the said permeable road. Both modelling efforts have deduced that the permeable road has 18,000 – 24,000 mm/hr of permeation rate when subjected to a 5-minute red-alert storm (>60mm/hr of intensity). It implies that StormPav green pavement has superior surface permeation against the forming of water ponding and flash flood on roads.

**Keywords:** CFD; Infiltration; Pavement; Rainfall; Runoff.

## 1. Introduction

The idea of changing the conventional roads to permeable one had been initiated since 1960s. Different permeable road models are introduced since then. For one, this paper introduces a new form of permeable road - a patent-pending Industrialized Building System (IBS) product named StormPav [1] (see Figure 1).

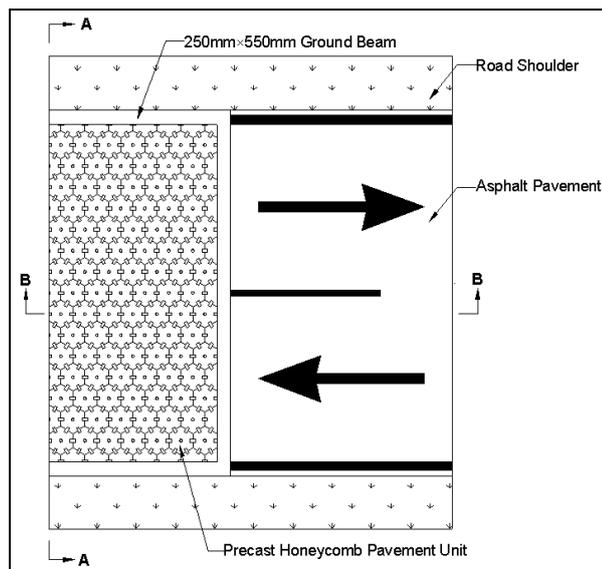

Fig. 1: StormPav Permeable Road

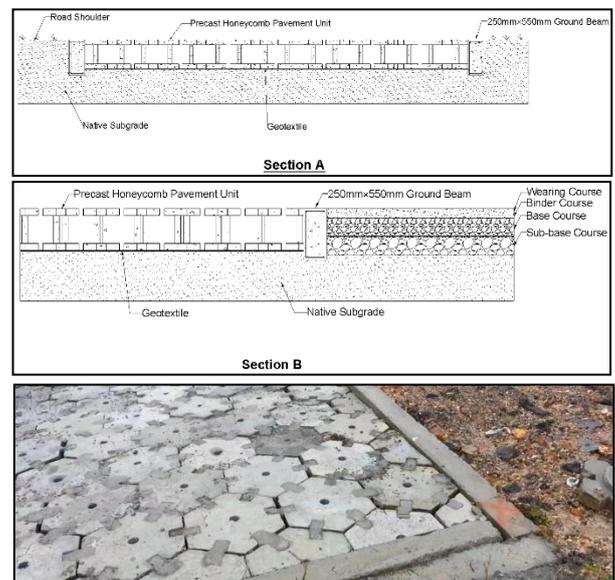

Fig. 1: Continued

StormPav consists of three precast concrete pieces to form a single modular unit, namely a top cover, a cylinder and a bottom plate (see Figure 2). Specially designed Grade 50 concrete mix is used to cast these pieces that could withstand crushing load up to 100 kN/unit. Utilization of the specialist concrete with high loading capacity has enable the fabrication of such a IBS modular unit. It has been designed to have hollow cylinders as the middle layer that function as temporary stormwater storage; and even with the intentional cavity, a single modular unit is proven strong enough in the laboratory to withstand heavy vehicle on top of it [2-3].

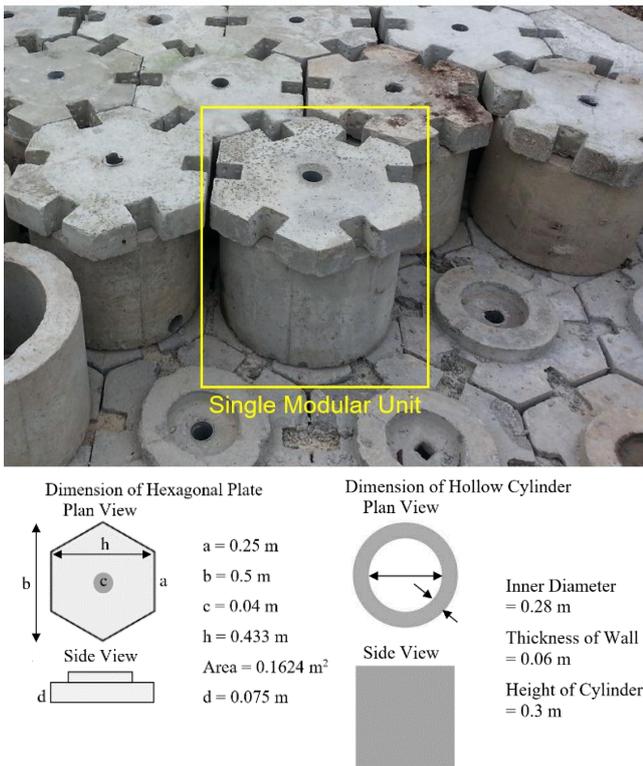

Fig. 2: Dimensions of StormPav modular unit

The modular units could hold water  $0.19\text{m}^3/\text{m}^2$  of pavement area [4]; in another word, fully capture 3-hour continuous 10-year Average Recurrent Interval (ARI) design storm. In the series of reporting findings of StormPav, an investigation is presented here about the capacity of the service inlet on the top cover to drain stormwater.

## 2. Surface Permeation

Hypothetically, stormwater could be penetrated to underground storage through internal voids or spaces that are provided on the road pavement. The presence of these opening cells is significant to make the pavement permeable. Basically, surface permeation of permeable pavement works according to the principle of capillary action, where the water seeps through the narrow spaces of interconnected voids. The term could be defined as “a measure of the water flow through the pore spaces or fractures” in the permeable medium [5].

As stated by [6], the performance of permeable pavement is prominently dependent on the void content of the pavement type. Take permeable concrete as an example, the void content is usually ranging from 15% to 35% of the concrete mix [7]. Another example, typical void content of permeable asphalt is almost the same as the former, at least 16% of air void content is specified to the total mix volume [8].

The higher the void content, the higher the surface permeation of permeable pavement. Yet the trend of surface permeation is also adversely affecting the strength of pavement. As a reference point, the design of permeable pavement should meet the requirements that are recommended by the local authority. As tabulated in Table 1, recommended values of surface permeation for permeable pavement are varied in different countries.

Table 1: Recommendations of surface permeation for permeable pavement

Source	Recommended Values for Surface Permeation
ASLA <sup>1</sup>	140+ in/hr (3,500+ mm/hr)
Credit Valley Conservation <sup>2</sup>	900 – 21,500 mm/hr
United Kingdom <sup>3</sup>	600 mm/hr

Malaysia <sup>4</sup>

For highest rainfall intensity of 598.9 mm/hr, average 4.2 minutes per 10cm depth (1430 mm/hr);

For lowest rainfall intensity of 12.4 mm/hr, average 4.3 hours per 10 cm depth (24 mm/hr).

## 3. Motivation

The service inlet on the StormPav top cover is a 40mm circular opening for surface permeation. Contrary to those in previous section, StormPav uses the principle of orifice flow that is significantly different than the former. This is the research gap for such a type of permeable pavement. When these top covers are assembled together, they form a flat surface with many holes that allow surface permeation to the underground storage. As such, it can be said that the interlocked top covers function as a multiple-orifice plate, which poses a discharge rate to the system to drain stormwater.

Industrial multiple-orifice plates are manufactured following the pipeline sizes. As illustrated in Figure 3, the volumetric flow rate per orifice (on the left) equals with each other, if they have a similar geometry and cross-sectional area [10-12].

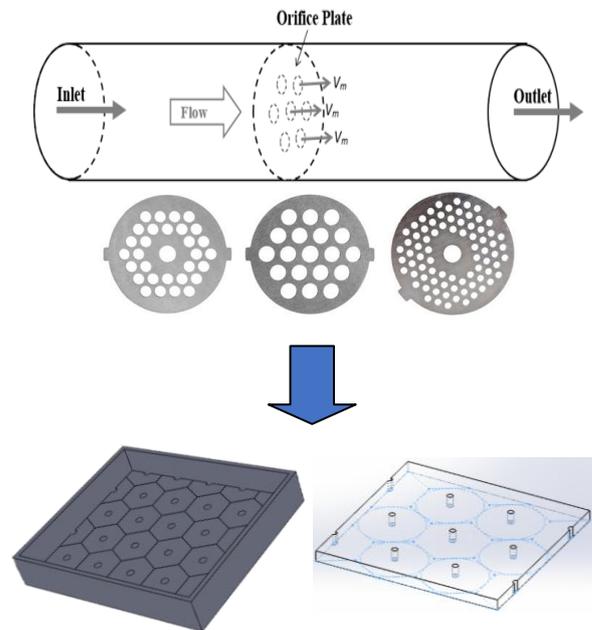

Fig. 3: Approach to surface permeation

However, the StormPav top covers (at the bottom of Figure 3) are demonstrating a trait peculiar to industrial orifice plates. As the number of orifice increases, the size of its surface area also increases, in which this could never happen in the pipeline industry to accommodate ever increasing pipeline sizes. In another word, the StormPav top covers present a case of unprecedented use of multiple-orifice plate that the existing formula may require modification. Therefore, it is reasonable to prescribe virtual and physical modelling to serve as a basis to understand orifice flow for such a new system.

## 4. Virtual Modelling

To accommodate virtual modelling of orifice flow, Computational Flow Dynamic (CFD) technique is applied to represent the Storm-

Pav system. The road surface and road kerb are modelled as a “big” rectangular pipe that flows vertically downward through an orifice plate (see Figure 4).

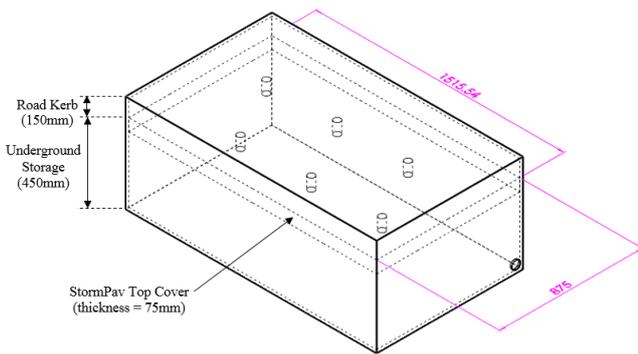

Fig. 4: CFD model of StormPav permeable road

For normal practice, 15-minute, 10-year ARI design rainfall is used for urban built environment. In this regard, the local weather data has it derived an intensity of 180 mm/hr. To make a realistic representation of rainfall, the 15-minute design storm is divided equally into three blocks of time period. Rainfall intensities of 57.6 mm/hr, 90.0mm/hr and 32.4 mm/hr are obtained accordingly. By doing so, three types of flow are computed as 0.02 l/s, 0.03 l/s and 0.01 l/s (see Table 2) respectively to be fed to both CFD simulation and laboratory testing for analysis.

Table 2: Design rainfall and peak runoff

Time Block	Rainfall Intensity (mm/hr)	Flow	
		Computational Step (m <sup>3</sup> /s) *	(l/s)
1 (0-5 min)	57.6	$Q_1=IA/3600$ $= [(57.6/1000) \times (0.875 \times 1.515)] / 3600$ $= 2.12 \times 10^{-5}$	0.02
2 (5-10 min)	90.0	$Q_2=IA/3600$ $= [(90.0/1000) \times (0.875 \times 1.515)] / 3600$ $= 3.31 \times 10^{-5}$	0.03
3 (10-15 min)	32.4	$Q_3=IA/3600$ $= [(32.4/1000) \times (0.875 \times 1.515)] / 3600$ $= 1.19 \times 10^{-5}$	0.01

\* By using Rational Formula  
 $Q = IA / 3600$   
 where I=rainfall intensity (in m/hr)  
 A=area intercepting the rainfall (in m<sup>2</sup>)

By using SolidWorks, the flows of 0.01 l/s, 0.02 l/s and 0.03 l/s are uniformly distributed through a 150 mm high road kerb to the orifice plate. Surface permeations through the orifice plate are found to be consistent with the theory, i.e. the rate equals with each other (see Figure 5).

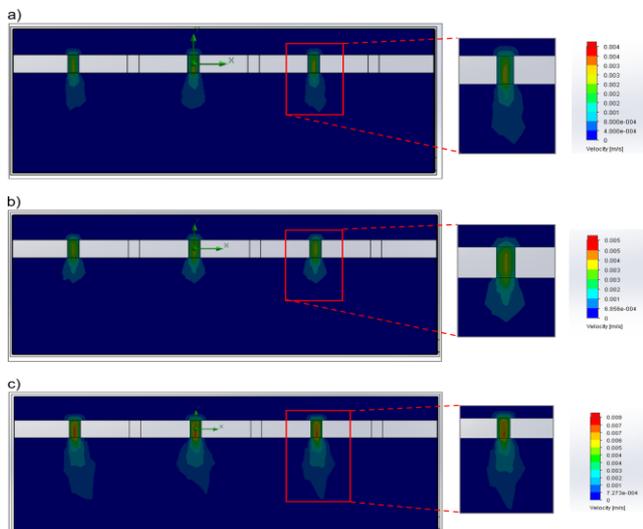

Fig. 5: Velocity profile through service inlet for flows a) 0.01 l/s, b) 0.02 l/s and c) 0.03 l/s

CFD simulations show that the surface permeation increases when the flow passing through increases. The efforts have estimated maximum velocities of 0.0025 m/s, 0.0036 m/s and 0.0067 m/s respectively; after being converted, they stand for 9,000 mm/hr, 12,960 mm/hr and 24,120 mm/hr through the orifice plate – a range more superior than any of those highlighted in Table 1.

### 5. Physical Modelling

In order to verify the CFD simulations, a laboratory testing is carried out. StormPav modular units are placed within a water tank of L1.67m x W1.09m x H0.60m (see Figure 6). Only six (6) full top covers could fit into the tank (Figure 6a), together with two (2) half covers and eight (8) triangular side covers. This justifies the size used in the CFD simulations earlier.

The half and side plates are substituted with acrylic plates, bound by another four (4) large acrylic plates at four sides to envelope the modular units and to represent road kerb. Gaps between the modular units are sealed with sealant and covered with duct tapes. Careful sealing at the sides is to ensure no water to seep through any spaces other than the six (6) service inlets (Figure 6b). Note that the CFD model only simulates six service inlets to be in line with this laboratory setting.

Fig. 6: Laboratory settings, a) Interlocking hexagonal plates, b) Rainfall simulator placed on top Of hexagonal plates, and c) Water dripping from rainfall simulator

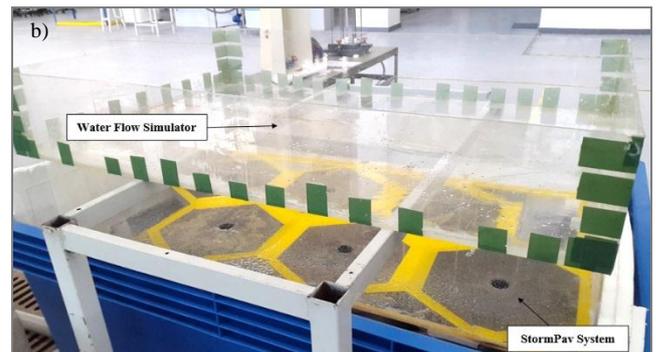

Fig. 6: Continued

A non-pressurized rainfall simulator is created with a smaller tank of L1.50m x W1.00m x H0.24m on top of the modular units. 2 mm diameter opening are drilled on the bottom of this tank. In order to simulate various rainfall intensities, the flow rate of the simulator is controlled by selectively closing the openings (visible on the top of Figure 6c). As a result, it is discovered that the increasing number of openings allowed the water to drain faster from the simulator tank and thus, a shorter time is required for a higher flow rate.

Twelve (12) openings over 5 l of water are adequate to simulate an intensity of 35 mm/hr; twenty (20) openings for 57 mm/hr; and thirty (30) openings for 90 mm/hr. Surface permeation processes of the service inlets are observed. Average velocities of 0.0021 m/s, 0.0030 m/s and 0.0051 m/s are recorded; after being converted, they stand for 7,560 mm/hr, 10,800 mm/hr and 18,360 mm/hr through the service inlets.

## 6. Discussion

Both CFD simulations and laboratory testing show that the orifice flow is highly dependent on rainfall intensity. The more runoff is generated, the more surface permeation is through the orifices. However, the values of simulation results are found to be larger than laboratory tests. For example, CFD result shows that each service inlet has the highest surface permeation of 24120 mm/hr (by converting the obtained velocity) at an inflow rate of 0.03 l/s, while the average value of laboratory tests is 31% lesser than that. Similarly, the surface permeation values obtained in the laboratory tests are 19% lower than CFD data for both inflow rates of 0.01 l/s and 0.02 l/s in Table 3.

In this regard, CFD simulations analyse the model as a full flow system in which the orifices are full of stormwater. Bear in mind that the CFD is taking the StormPav system as a rectangular pipe flow. As illustrated in Figure 5, this phenomenon can be seen in the simulation results as there are three (3) water ponding scenarios to enable the stormwater to have a full flow in all orifices. However, water ponding is not observed in the laboratory testing as the stormwater permeates into the underground chambers through the edges of orifices. As demonstrated in Figure 6, rainfall simulator in the laboratory testing is using the dripping method. As volume of water on the pavement surface is more critical to represent the surface runoff than the rain drop sizes, this method is appropriate.

**Table 3:** Comparisons of surface permeation

Rainfall Intensity (mm/hr)	CFD Simulation	
	(m/s)	(mm/hr)
32.4	0.0025	9000
57.6	0.0036	15840
90.0	0.0067	24120

Rainfall Intensity (mm/hr)	Laboratory Testing					Difference (%)
	1	2	3	Average		
	(m/s)	(m/s)	(m/s)	(m/s)	(mm/hr)	
35	0.0021	0.0020	0.0023	0.0021	7560	-19
55	0.0037	0.0038	0.0036	0.0037	13320	-19
90	0.0050	0.0048	0.0053	0.0051	18360	-31

As such, the authors identify a limitation of the CFD simulation of flow through StormPav system. Surface permeations by CFD are 19 - 31% higher compared to the laboratory testing. In fact, CFD has a constraint in simulating flow only at the edges of orifices. Having said so, it is common in flow modelling of environmental systems that a correlation of 0.6 is acceptable when comparing the modelled and observed hydrographs (for example in the engineering manual of US Army Corps of Engineers), in which a difference of up to 40% is accepted due to complexity in the actual environmental processes. Based on the mentioned precedence, the difference of up to 31% demonstrated in the CFD could be taken as acceptable as well.

## 7. Conclusion

There are significant differences between the CFD simulations and laboratory testing, as high as 31%. In the absence of better computer modelling technique, the employed applied methods could not provide a solution to improve the existing formula of multiple-orifice plate to accommodate StormPav road. Yet, both efforts have shown that the multiple-orifice permeable road has a superior quality in surface permeation and an estimation of 18,000 – 24,000 mm/hr has been derived.
